Abstract

Objective: The objective of the current work is to synthesize the conducting polymer, i.e. polyaniline electrodes, with different reaction times using the chemical bath deposition (CBD) method. The further study involves its effect on structural, morphological, and electrochemical characteristics of the PANI electrodes.

Methods: The CBD method is used to synthesize the PANI electrodes. The analysis of the electrodes was carried out using X-Ray diffraction, contact angle, FESEM with EDX, Fourier-transform infrared spectroscopy, and electrochemical characterizations.

Results: The structural and wettability analysis confirmed the amorphous and hydrophilic properties of the PANI electrodes. The contact angle increased with an increase in the reaction time of the PANI electrodes. The morphological images of all samples showed that the thickness of the interconnected nanofibres increased with the deposition time. Electrochemical analysis of the PANI electrodes was carried out by cyclic voltammetry (CV), galvanostatic charge-discharge (GCD), and electrochemical impedance spectroscopy. The evaluated highest value of specific capacitance (SC) by CV was 601F/g at 5mV/s in 1M KOH. GCD provided specific energy of 9.10Whg⁻¹, specific power of 22kW kg⁻¹, and an efficiency of 92.89%.

Conclusion: It is feasible to synthesize PANI samples with the CBD method. The physical and electrochemical properties of electrodes prepared at different deposition times change with increasing deposition times. Deposition time does not affect the amorphous nature of the sample, and the sample deposited for 60min exhibited the highest SC 601F/gm at 5mVs⁻¹.

Keywords: polyaniline, chemical bath deposition, electrochemical study, time variation

1 INTRODUCTION

The supercapacitor is a novel energy storage device with high energy and power. Hence, it is usually utilized for energy storage and power delivery. Electrochemical supercapacitors are (a) Electric double layer capacitors (EDLCs) that stores charges electro-statically at the electrode-electrolyte boundary, (b) pseudo-capacitor stores that charge electrochemically, and (c) hybrid Supercapacitor that stores charges electrostatically and electrochemically. Generally, carbon-based materials are preferred as electrode materials for EDLCs\cite{1-4}, whereas the composites and transition metal oxides conducting polymers (CPs) were for pseudo-capacitors\cite{2}.

Recently, CP has seen significant demand in the technology sector. There are various CPs used in supercapacitors, actuators, and electronic devices, such as polythiophene, polyaniline (PANI), polypyrrole, polyacetylene, and polypindole. The organo-metallic composites, organic materials, and polymers have been employed in batteries and supercapacitors\cite{4-9}. The different electrical CPs have also been used in batteries and supercapacitors\cite{10-13}. PANI is synthesized either by chemical oxidative polymerization or electrochemically oxidative polymerization\cite{14}. Synthesis of the PANI electrode can be done by multiple methods such as spray pyrolysis\cite{15}, electrodeposition\cite{16}, chemical vapour deposition\cite{17}, and chemical bath deposition (CBD)\cite{19}. The PANI is seen as a suitable electrode material because of its high electrical conductivity, water-soluble monomer, good environmental stability, room-temperature synthesis, good redox reversibility, and high charge storage ability\cite{19}. PANI is the most advantageous CP used for various electrochemical devices such as electrochemical supercapacitors, fuel cells, and batteries\cite{20}. Belanger et al observed a 5% loss of specific capacitance (SC) of PANI up to 20,000 cycles\cite{21}. Amongst all methods, CBD is exceptionally manageable and cost-effective and does not require any sophisticated instrumentation. Thus, the present study focused on the synthesis of PANI on the stainless steel (SS) current collector at various dip times by CBD technique. Physical and electrochemical analyses were performed on the prepared samples to optimize the sample electrodes.

2 MATERIALS AND METHODS

2.1 Synthesis of PANI

Aniline, sulfuric acid, and ammonium peroxysulfate (APS) used for synthesis were purchased from Sigma-Aldrich. All reagents are of AR grade. The deposition bath was prepared with 1M (40mL) aniline, 1.5M (40mL) H₂SO₄ and 1.25M (20mL) APS dissolve separately in double distilled water (DDW). Oxidizing agents such as ammonium dichromate, ammonium peroxysulphate, ammonium cerium, nitrate mixture, and hydrogen peroxide were used. Among all these oxidizers APS can form cation-radicals from aniline monomers that are used to initiate the polymerization of PANI, and APS also yields larger polymer chains within an extremely short reaction time. Here, APS acts as an oxidizing agent in the polymerization of aniline at various deposition periods. The well-polished conducting SS substrates were used as a current collector for the deposition of PANI. The deposition was carried out at room temperature at the constant stirring of 1500rpm for 60, 90, 120, 150, and 180min. The deposition time periods varied because uniform and adherent PANI thin films were expected. Initially, the bath solution is bluish in color and over time, it turns green in color due to the polymerization of aniline (Figure 1). After completion of the deposition process, samples were washed using DDW three to four times to remove loosely bound particles and then dried at room temperature. These prepared samples were denoted as MN₁, MN₂, MN₃, MN₄, and MN₅.

2.2 Growth Mechanism of PANI Thin Films

The deposition techniques of thin-film deposition can be divided into two groups based on the nature of the deposition process viz, physical or chemical methods. Among all these methods, the CBD technique is well known and of simple operation. For the chemical polymerization of the solution, monomers must be oxidized initially, as shown in schematic Figure 1.

Oxidation of the aniline monomer with oxidizing agent generates radical cations for further polymerization. The oxidizing agent removes a proton from an aniline monomer. The addition of the proton takes place by adding protonic acid at the completion of the polymerization reaction. The same was observed by Saini et al\cite{22}. The emeraldine form is associated with the partially oxidized or reduced state. They are distinguished by four different colors, namely, Leucoemeraldine- white/clear and colorless, Emeraldine salt- green, Emeraldine base-blue, Pernigraniline- blue/violet. The prepared PANI thin-film electrodes showed blue-green in color. The possible chemical reaction is as in Figure 2.

2.3 Characterizations

The prepared PANI thin films were characterized by different characterization techniques. The surface morphology and energy dispersive X-ray were analyzed by Field Emission Scanning Electron Microscopy (FE-SEM). The crystallographic studies of deposited PANI thin-film electrodes were analyzed using the diffractometer (Ultima IV Rigaku D/max 2550Vb+18kw with CuKa radiation λ=1.54056 Å, Japan) with diffraction angles of (2q) 20°-80°. The thickness of PANI thin films was measured by the conventional weight difference method using a highly sensitive analytical

3 RESULTS AND DISCUSSION

3.1 X-ray Diffraction

Figure 3 depicts the X-ray diffraction pattern of the synthesized PANI electrodes. All samples exhibited the same amorphous nature, indicated by XRD patterns. The amorphous nature of the PANI electrode contributed to the better performance of the electrochemical capacitive device.

3.2 Wettability Study

To study the wettability nature of the prepared PANI films, contact angle measurement was conducted for all samples (Figure 4). In this process, a liquid electrolyte drop was kept on the sample surface, and a contact angle meter was used to photograph the interaction of the liquid with the sample surface.

3.3 Fourier-Transform Infrared Spectroscopy (FTIR)

FTIR patterns of prepared PANI electrodes show a number of peaks (Figure 5). The molecular structure of PANI samples displays a range of 4000 to 500cm⁻¹.
The IR bands (3210, 3262cm⁻¹) show N-H stretching vibrations, and C-H stretching vibrations are observed in CH₃ at 2971, 2935cm⁻¹. C-H vibrations in CH₂ are observed at 2862, 2854cm⁻¹, and C≡N stretching vibrations of the quinoid ring are observed at 1739cm⁻¹. The peaks at 1571 and 1574 cm⁻¹ show stretching vibrations in an aromatic primary ring, at 1415 and 1571 cm⁻¹, stretching vibrations of the benzene ring are observed. The peak at 1451 cm⁻¹ shows C≡N stretching vibrations. The peak at 1301 cm⁻¹ shows C-N stretching vibrations of aromatic ring, at 1206 cm⁻¹ shows stretching vibrations in an aromatic primary ring, at 1100 and 1118 cm⁻¹ shows plane bending vibrations of aromatic C-H, at 913 cm⁻¹ shows quinoid ring -NH - benzoic ring stretching vibrations, at 904 cm⁻¹ shows C-H out of the plane bending vibrations, at 810 cm⁻¹ and 671 cm⁻¹ shows meta substitutions, 1,3 disubstitution in benzene ring, at 713, 501 cm⁻¹ shows ortho substitutions, 1,2 disubstitutions in benzene ring, and at 608, 603 cm⁻¹ vibrations in aryl nitro compounds are observed. Therefore, it can be concluded that the samples obtained are PANI.

3.4 FE-SEM and EDX Spectra of PANI

The surface morphology of the CBD method prepared by diffused interconnected nanofibres samples is studied by FE-SEM images, as shown in Figure 6 MNₓ-MNₙ. From FE-SEM images, nanofibres are diffused and are highly porous with a mean diameter of 40nm to 160nm, providing a large surface area for supercapacitor.

Figure 6 (MNₓ-MNₙ) shows the surface morphology variations of PANI electrodes, which are observed using FE-SEM at 5000x. With an increase in dip time, the morphology changes from a compact dense mud-like structure to a large number of diffused nanofibres produced, and the size of nanofibres also are changed. Such porous diffused nanofibres morphology definitely enhances the performance of PANI films. Figure 6 (MNₙ) shows surface morphological images of 180min (MNₙ), which displays a mud-like structure with an extremely small particle size of nearly 40 to 50cm nm. Figure 4 (MNₓ-MNₙ) time period (150-120min) for the deposition of the synthesized PANI electrode material on the SS substrate decreases, the number of diffused nanofibres increases and the size of the nanofibers is 55nm to 100nm. Further, the time was again reduced to 90-60min (MNₙ to MN₁), the PANI material was converted to a very large number of diffused nanofibres, and the size was also increased by 109nm to 159.6nm, as observed in FE-SEM image Figure 6 (MN₁).

Figure 6 shows that MN₁, MNₙ PANI shows a very large number of diffused nanofibres and an increase in size from 109nm to 159.6nm, as observed in FE-SEM image Figure 6 (MN₁). This porous diffused nanofibres nature is vital for the better performance of electrochemical supercapacitor application, as it provides an improvement in the surface area of the electrodes. Again, the porous structure of the nanofibers decreases with increasing time. MNₙ displays extremely long nanofibres of nearly 159.6nm, which helps to store more charge in the active electrode (PANI), as most of the active electrode materials undergo pseudocapacitive behavior.

The FE-SEM images show that the number of nanofibers decreases with increasing deposition time. The diffuse interconnected nanofiber morphology is obtained at 60min of the MN₁ polymerization. With the increase in polymerization time, the conversion of nanofibers decreases and becomes a compact mud-like structure. The corresponding EDX spectra and SEM images in Figure 6 show only N, O, H, and a C element signal in weight percentage and atomic percentage.

3.5 Electrochemical Analysis

3.5.1 CV Study

CV is used to analyze the capacitive behavior of synthesized PANI samples. Figure 7A shows CV curves of MN₁, MN₃, MN₅, MN₇, and MN₉ electrodes at the scan rate of 5mVs⁻¹ within -1.5 to 0.5V in 1M KOH aqueous electrolyte. It indicates the significant differences in the CV curves of different PANI samples. The SC values of PANI samples were estimated using the following relation:

\[ SC = \frac{c \cdot \Delta V \cdot \Delta t}{W \cdot \ln 2} \cdot \frac{1}{\Delta V} \] (1)

The estimated SC values for PANI MN₃, MN₅, MN₇, MN₉, and MN₉ samples at 5mVs⁻¹ scan rate are given in Table 1. Sample MN₉ produces the highest SC value. Further CV curves of the MN₉ sample at different scan rates of 5, 10, 20, 50, and 100mVs⁻¹ are shown in Figure 7B for the MN₉ PANI electrode. The redox peaks seen in the curves are due to oxidation and reduction of active
sites at the electrode. The arrival of redox peaks indicates the pseudocapacitive nature of the PANI electrodes\(^\text{[15]}\). The calculated SC values for the MN\(_1\) electrode at different scan rates are given in Table 1. The sample MN\(_1\) exhibits the highest SC of 601 F/g at 5 mV/s\(^{-1}\). With the rise in the scan rate, the current response also increases, which is a sign of ideal capacitive behavior. The value of SC decreases with increasing scan rate, which indicates the existence of the inner active materials that do not undergo the redox reactions in bulk materials, as well as the inaccessibility of the electrode surface reactive materials at higher charge and discharge rates\(^\text{[37]}\). Figure 7C shows variation in SC values of PANI samples with the scan rate.

### 3.5.2 GCD Study

The GCD analysis also helps to test the performance of electrochemical behavior of the PANI samples. Figure 8A and B show the GCD curves of PANI samples in an aqueous 1 M KOH within the potential range of -1.2 to 0.5 V. Figure 8A clearly shows that the charging and discharging curves of all samples at different current densities are not symmetrical and exhibit a pseudocapacitive nature. Similar behavior has been observed by Thokale et al\(^\text{[41]}\).

Specific energy and specific power of PANI samples were calculated using GCD curves and are estimated by the following relations\(^\text{[2-4]}\):

\[
\text{Specific energy, } SE = \frac{(l_0 \times T_d \times V)}{W} \quad (2)
\]

\[
\text{Specific power, } SP = \frac{(l_0 \times V)}{W} \quad (3)
\]

\[
\text{Efficiency, } \eta = \frac{(T_d / T_f)}{100} \quad (4)
\]

Figure 9. MN1 sample analyzed using the electrochemical impedance analyzer/spectrometer. A: Nyquist plot of optimized MN$_1$ sample; B: An ESR; C: Bode plot; D: Matched nyquist plot.

3.5.3 Electrochemical Impedance Spectrometry (EIS)

EIS is a fundamental technique used for the analysis of resistive and capacitive behaviors of material used in supercapacitors. Figure 9 shows the Nyquist plot of the optimized MN$_1$ sample analyzed using the electrochemical impedance analyzer/spectrometer in an aqueous 1M KOH electrolyte solution operated at an AC frequency of 1MHz to 1mHz. The higher frequency region consists of the faradic resistance, charge transfer resistance (Ret), or electrolyte resistance. In a lower frequency region, the electrolytes diffuse to the active electrode sites, creating diffusion resistance called Warburg resistance. The electrolyte resistance, i.e. an equivalent series resistance (ESR), is composed of the ionic resistance of the KOH, the resistance of the SS, and the contact resistance of the deposited PANI and SS. Ret is observed in the redox reaction between the electrode material and the electrolyte[38]. The total internal resistance or ESR of the MN$_1$ sample is observed to be 1.30Ω/cm$^2$.

4 CONCLUSION

In a CBD method, it is possible to synthesize PANI samples at different deposition times. The deposition time does not affect the amorphous nature of the samples. It was observed that the sample deposited for 60min...
showed the highest SC value of 601F/gm at 5ms⁻¹. The morphology changed from compact mud-like to diffused nanotube with deposition time. All deposited samples were hydrophilic. The observed highest specific energy was 9.10WHg⁻¹, the specific power was 22.08kWkg⁻¹, and the coulombic efficiency was 92.89%. Overall, a sample, deposited for 60min, exhibited good capacitive behavior.
